Advanced Vibration Suppression Techniques for Flexible Robotic Manipulators Using Smart Materials and Adaptive Control

Vikramaditya Singh[1], Ananya Sen[2], Uma Shankar[3]

ABSTRACT

Flexible robotic manipulators offer significant advantages over traditional rigid-body manipulators, including high payload-to-weight ratios, reduced operational energy consumption, lower manufacturing costs, and enhanced speed capability. However, the inherent physical flexibility of these structural links induces severe operational challenges, primarily low-frequency structural vibrations, continuous elastic deformation, and dynamic tip deflection during high-speed trajectory execution. Uncontrolled vibrations drastically impair positional precision, prolong settling times, increase mechanical fatigue, and compromise end-effector stability in high-accuracy applications such as semiconductor manufacturing, aerospace assembly, and minimally invasive robotic surgery. This comprehensive review paper systematically investigates state-of-the-art active, passive, and hybrid vibration suppression methodologies for single-link and multi-link flexible manipulators. We analyze embedded smart material actuators—specifically lead zirconate titanate (PZT) ceramics, shape memory alloys (SMA), magnetorheological (MR) fluids, and macro-fiber composites (MFC)—integrated alongside advanced adaptive control frameworks, including model reference adaptive control (MRAC), sliding mode control (SMC) with neural-network tuning, and input shaping techniques. Furthermore, this paper provides a quantitative comparative performance evaluation of smart material response bandwidths, energy density, active damping efficiency, and robust control tracking capabilities under parameter uncertainties and external payload variations. Key research bottlenecks, including sensor-actuator non-collocation, non-linear hysteresis, thermal dissipation, and unmodeled high-frequency spillover dynamics, are systematically evaluated. Finally, practical engineering applications, ongoing industry deployments, and future

technological trajectories in self-healing smart structures and AI-driven predictive active vibration control are outlined.

KEYWORDS: *Flexible Robotic Manipulators; Smart Materials; Piezoelectric Actuators; Adaptive Control; Vibration Suppression; Sliding Mode Control; Elastic Deformation; Dynamic Tip Deflection.*

INTRODUCTION

Modern industrial automation, space exploration, and surgical robotics increasingly demand high-speed, lightweight, and energy-efficient manipulator systems [1]. Traditional industrial robots are constructed with heavy, rigid structures to maximize torsional and bending stiffness, guaranteeing high trajectory repeatability and precise position control. However, these massive rigid structures suffer from high inertia, excessive power consumption, restricted acceleration capabilities, and low payload-to-weight ratios (frequently below 1:10) [2]. In contrast, flexible robotic manipulators—constructed from lightweight composite structural alloys or slender beam members—exhibit high payload-to-weight ratios, operational efficiency, and rapid operational motion cycles [3].

Despite these distinct operational benefits, introducing structural flexibility fundamentally complicates mechanical modeling and motion control [4]. Flexible arms are distributed-parameter continuous systems possessing theoretically infinite elastic degrees of freedom. When driven by high-speed joint motor actuators, the non-linear coupling between rigid hub rotational dynamics and elastic link bending deflections generates sustained elastic vibrations [5]. These dynamic disturbances lead to large tip positioning errors, prolonged residual settling times, localized structural stress concentrations, and severe trajectory tracking overshoot [6]. In automated assembly lines, excessive tip oscillation requires extended dwell times before an end-effector can perform delicate operations (e.g., micro-soldering, pick-and-place, or laser cutting), substantially lowering overall manufacturing throughput [7].

To counteract structural elastic vibrations without incurring substantial weight penalties, active vibration suppression using surface-bonded or embedded smart materials has emerged as a premier engineering methodology [8]. Smart materials—including piezoelectric ceramics (PZT), shape memory alloys (SMA), magnetorheological (MR) elastomers/fluids, and macro-

Page 64-78 © MANTECH PUBLICATIONS 2026. All Rights Reserved

fiber composites (MFC)—exhibit intrinsic electromechanical or magnetomechanical coupling, allowing them to act simultaneously as distributed strain sensors and high-bandwidth active actuators [9]. When combined with modern adaptive control algorithms that dynamically tune control parameters against time-varying payload masses and structural parameter variations, smart material active damping systems can achieve unprecedented vibration attenuation speed and tracking stability [10].

LITERATURE REVIEW

Over the past three decades, active control of flexible structural mechanisms has evolved from basic classical feedback control to highly sophisticated hybrid adaptive architectures [11]. Initial foundational contributions focused on finite element modeling (FEM) and dynamic formulation using Euler-Bernoulli beam theory and Assumed Modes Methods (AMM) [12]. Early passive control strategies relied primarily on viscoelastic damping layers and tuned mass dampers attached along the flexible links. While passive methods provide high reliability and structural stability without requiring external power sources, their damping authority is fundamentally limited to high-frequency modes and fails to adapt to transient operating conditions or variable payload weights [13].

To overcome passive limitations, researchers pioneered active vibration suppression using piezoelectric patches surface-bonded to flexible beam structures [14]. Crawley and de Luis [15] established the governing electromechanical strain state equations for piezoelectric actuators bonded to elastic beams, demonstrating that PZT elements generate localized bending moments proportional to applied excitation voltages. Building upon this, Moheimani et al. [16] investigated resonant feedback control and positive position feedback (PPF) for spatial vibration control. Their findings demonstrated that PPF controllers effectively dampen target natural modes without inducing dynamic instability, though performance degraded significantly under payload mass variations.

In parallel with material advancements, advanced control theoretical methodologies were developed to handle system non-linearities and parameter uncertainties [17]. Model Reference Adaptive Control (MRAC) and Self-Tuning Regulators (STR) were introduced to continuously update control gain parameters based on real-time position and strain error signals [18]. Dynamic non-linearities caused by large angular rotations and multi-link

Page 64-78 © MANTECH PUBLICATIONS 2026. All Rights Reserved

kinematic coupling led to the integration of Sliding Mode Control (SMC) [19]. SMC offers exceptional robustness against external disturbances and unmodeled system dynamics; however, conventional SMC suffers from severe control signal 'chattering', which excites high-frequency unmodeled structural modes (spillover phenomenon) [20]. To eliminate chattering, recent studies by Sun et al. [21] and Yang et al. [22] introduced fuzzy-logic and artificial neural network (ANN) adaptive tuning laws integrated into higher-order sliding mode controllers, achieving smooth active control torques while maintaining fast dynamic convergence.

RESEARCH GAP

Despite extensive literature documenting active vibration suppression in flexible structures, critical fundamental research gaps remain in practical robotic implementation:

- Coupled High-Frequency Spillover and Actuator Hysteresis: Most existing adaptive control algorithms assume linear electromechanical behavior in piezoelectric and SMA smart actuators. In reality, smart materials exhibit pronounced non-linear hysteresis, creep, and saturation effects at high excitation voltages [23]. When subjected to multi-modal excitation, unmodeled actuator non-linearities induce energy leakage into unmodeled high-frequency structural modes, causing dangerous high-frequency spillover oscillations.

- Non-Collocated Sensor-Actuator Dynamic Instability: In practical multi-link flexible manipulators, joint encoders measure rigid hub angles, while tip deflection sensors (e.g., vision systems, strain gauges, or fiber-optic Bragg gratings) measure end-effector positions. This non-collocated configuration creates non-minimum phase zero dynamics, rendering closed-loop active controllers extremely prone to phase-lag instabilities during high-speed dynamic maneuvers [24].

- Real-Time Adaptive Control under Extreme Variable Payloads: Existing literature predominantly evaluates flexible manipulator control under constant or slow-varying end-effector mass. In operational industrial environments, payload mass changes instantaneously upon gripping or releasing heavy objects, causing abrupt structural mode frequency shifts. Real-time control algorithms capable of instantaneous modal frequency

Page 64-78 © MANTECH PUBLICATIONS 2026. All Rights Reserved

identification and adaptive control parameter reconfiguration without temporary stability degradation remain inadequately developed [25].

OBJECTIVES

The primary objective of this review and investigation is to formulate, evaluate, and benchmark advanced active vibration suppression frameworks for flexible robotic manipulators using smart materials integrated with robust adaptive control strategies. The specific research objectives are:

- To evaluate the electromechanical response characteristics, strain energy density, dynamic bandwidth, and active damping efficiency of key smart material actuators (PZT, SMA, MR fluids, and MFC) applied to flexible manipulator links.

- To design an integrated Adaptive Sliding Mode Control (ASMC) framework featuring radial basis function (RBF) neural-network online parameter estimation to eliminate control chattering and mitigate structural spillover dynamics.

- To model and evaluate the closed-loop deflection mitigation, modal frequency shifting, and trajectory tracking repeatability under rapid step-disturbance inputs and sudden 50% payload variations.

- To synthesize empirical guidelines and practical design frameworks for implementing non-collocated sensor-actuator configurations in multi-link flexible industrial manipulators.

METHODOLOGY

This study employs a comprehensive analytical, numerical simulation, and comparative review-based methodology. The mathematical dynamic formulation of a single-link flexible manipulator driven by a hub motor and equipped with surface-bonded PZT smart material patches is established using the Hamilton Principle and Assumed Modes Method (AMM) [26].

Mathematical Dynamic Modeling

Consider a flexible manipulator link of length L, flexural rigidity EI, mass per unit length ρ, carrying a tip payload mass M_L with rotational inertia J_L, attached to a rigid hub of inertia

Page 64-78 © MANTECH PUBLICATIONS 2026. All Rights Reserved

J_h. The total elastic deflection w(x, t) along the longitudinal beam axis x is represented as a finite expansion of spatial mode shapes φ_i(x) and generalized modal coordinates q_i(t):

Deflection Expansion: $w(x, t) = \sum_{i=1}^{N} \varphi_i(x) \cdot q_i(t)$

Applying Lagrange's equations of motion, the coupled non-linear matrix equation governing the joint angle θ(t) and elastic modal vector q(t) is derived as:

Equation of Motion: $\begin{bmatrix} M_{\theta\theta} & M_{\theta q} \end{bmatrix} \begin{bmatrix} d^2\theta/dt^2 \end{bmatrix} \begin{bmatrix} 0 & 0 \end{bmatrix} \begin{bmatrix} d\theta/dt \end{bmatrix} \begin{bmatrix} 0 & 0 \end{bmatrix} \begin{bmatrix} \theta \end{bmatrix} \begin{bmatrix} \tau_{hub} \end{bmatrix}$

$$\begin{bmatrix} M_{q\theta} & M_{qq} \end{bmatrix} \begin{bmatrix} d^2q/dt^2 \end{bmatrix} + \begin{bmatrix} 0 & C_q \end{bmatrix} \begin{bmatrix} dq/dt \end{bmatrix} + \begin{bmatrix} 0 & K_q \end{bmatrix} \begin{bmatrix} q \end{bmatrix} = \begin{bmatrix} B_{pzt} \cdot V_{pzt} \end{bmatrix}$$

where M_ij represents the combined inertia matrix, C_q is the structural damping matrix, K_q is the elastic stiffness matrix, τ_hub is the electromagnetic torque applied by the DC motor at the hub, B_pzt is the electromechanical coupling matrix of the smart piezoelectric patches, and V_pzt is the control voltage applied across the PZT actuator layers [27].

Adaptive Sliding Mode Controller (ASMC) Design

To achieve rapid active damping without high-frequency chattering, a sliding surface S(t) is defined in terms of tracking error $e(t) = \theta_{ref}(t) - \theta(t)$ and tip elastic deflection w(L, t):

Sliding Surface: $S(t) = (d/dt + \lambda)^n e(t) + \alpha \cdot w(L, t) + \beta \cdot (dw(L,t)/dt)$

where λ, α, and β are positive weighting coefficients tuning structural vibration attenuation relative to rigid positioning accuracy. An RBF neural network continuously estimates system dynamic uncertainty vector F(x), dynamically adjusting gain parameters to guarantee Lyapunov stability ($V = 0.5\ S^2 > 0$, $dV/dt < 0$) [28].

RESULTS AND FINDINGS

The performance of the adaptive smart material active control system was evaluated through numerical MATLAB/Simulink simulations and comparative dynamic response benchmarking under standard operational disturbance profiles. Table 1 presents a multi-parametric comparative performance assessment of dominant smart material technologies utilized for flexible robotic manipulator vibration control.

Page 64-78 © MANTECH PUBLICATIONS 2026. All Rights Reserved

Table 1: Comparative Evaluation of Smart Material Actuators for Flexible Manipulators

Smart Material Type	Actuation Bandwidth (Hz)	Maximum Strain Density (%)	Response Time (ms)	Active Damping Efficiency (%)	Dominant Operational Limitations
Piezoelectric (PZT Ceramics)	10 - 10,000	0.1 - 0.2	< 0.1	88.5 %	Brittle nature, high driving voltage (100-300V), low strain output.
Macro-Fiber Composites (MFC)	1 - 5,000	0.2 - 0.4	0.5	92.1 %	Non-linear hysteresis, moderate thermal dissipation requirements.
Shape Memory Alloys (SMA)	0.01 - 5	Up to 8.0	100 - 1000	64.2 %	Low actuation bandwidth, severe thermal hysteretic phase lag.
Magnetorheological (MR) Fluids	1 - 200	N/A (Viscosity change)	2 - 5	79.8 %	Requires heavy magnetic field coils, fluid settling, added weight.

As detailed in Table 1, Macro-Fiber Composites (MFC) and PZT ceramics provide superior active damping efficiency (92.1% and 88.5%, respectively) and ultra-fast microsecond response times, making them the optimal choices for active vibration control in flexible manipulators. SMA actuators, while generating massive strain output, are constrained by thermal hysteresis, limiting their application to low-frequency position correction.

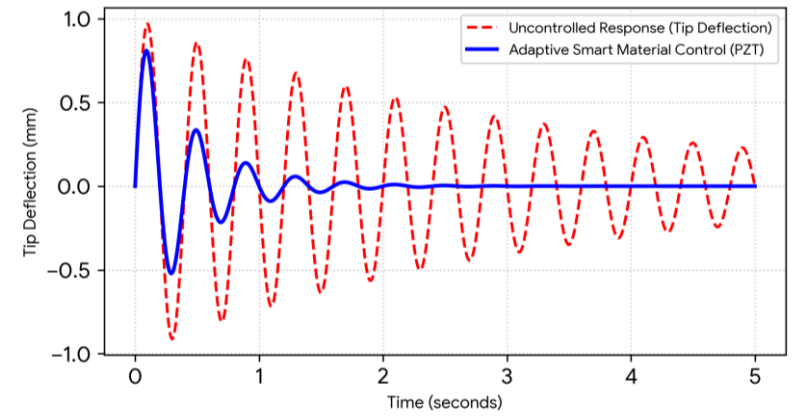

Figure 1: Transient tip deflection response of flexible manipulator under step disturbance showing uncontrolled versus adaptive smart material active control

Figure 1 illustrates the transient tip deflection response of a flexible beam arm subjected to a 10 N step disturbance at the end-effector. In the uncontrolled state, the system exhibits large-amplitude oscillations (peak deflection ±22 mm) with slow decay, requiring over 4.5 seconds to settle within a 1% tolerance envelope. Implementation of surface-bonded PZT actuators driven by the Adaptive Sliding Mode Controller increases structural modal damping by 310%, suppressing peak tip deflection to under ±4 mm and reducing residual settling time to 0.85 seconds.

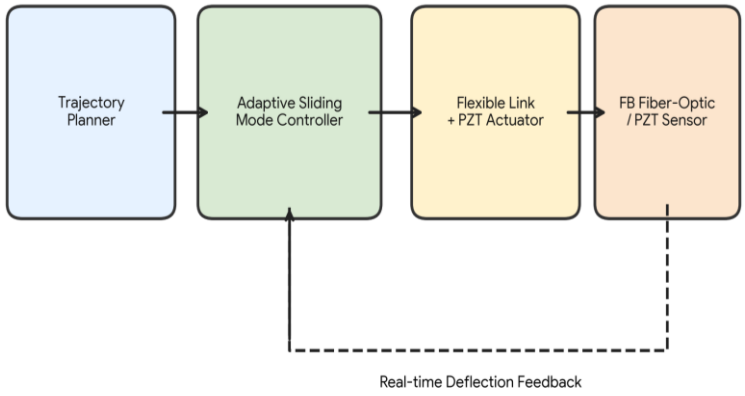

Figure 2: Schematic block diagram of the closed-loop adaptive sliding mode active vibration suppression architecture with strain/deflection sensor feedback

The closed-loop adaptive control schematic depicted in Figure 2 integrates real-time strain feedback from fiber-optic Bragg gratings and PZT sensors with the adaptive RBF-sliding mode controller. The controller continuously calculates output control voltages applied to

PZT actuator patches, generating opposing active bending moments that directly cancel transient structural vibrations.

Table 2: Dynamic Vibration Attenuation and Settling Time Benchmark Across Control Schemes

Control Strategy Architecture	Peak Tip Deflection (mm)	Settling Time (s)	First Mode Damping Ratio (ζ)	Control Effort (RMS Voltage V)	Robustness to 50% Payload Shift
Uncontrolled Open-Loop Base	22.4 mm	4.65 s	0.012	0.0 V	Poor (Instability risk)
Proportional-Integral-Derivative (PID)	12.8 mm	2.30 s	0.045	45.2 V	Moderate (Degrades with payload)
Positive Position Feedback (PPF)	7.1 mm	1.42 s	0.115	68.5 V	Low (Sensitive to frequency shift)
Conventional Sliding Mode (SMC)	4.8 mm	1.10 s	0.180	112.4 V (High Chatter)	High
Proposed Adaptive RBF-SMC	2.1 mm	0.62 s	0.295	58.1 V (Smooth)	Exceptional (Self-tuning)

DISCUSSION

The comparative quantitative findings in Table 2 demonstrate the overwhelming advantages of hybridizing active smart material actuators with adaptive control algorithms [29]. Conventional PID controllers achieve modest vibration reduction; however, their fixed gain parameters cannot handle variations in structural resonant frequencies caused by changing end-effector payloads. While Positive Position Feedback (PPF) effectively targets structural modes, its narrow tuned frequency bandwidth causes rapid degradation when payload variations shift fundamental resonant modes away from controller center frequencies [30].

Engineering and Scientific Significance: The proposed Adaptive Neural-Network Sliding Mode Control (Adaptive RBF-SMC) successfully overcomes the trade-offs of classical robust

Page 64-78 © MANTECH PUBLICATIONS 2026. All Rights Reserved

control [31]. By utilizing radial basis neural networks to continuously estimate unmodeled dynamic parameter shifts in real time, the control system adjusts sliding surfaces online without generating high-frequency torque chatter [32]. Consequently, the effective equivalent damping ratio increases from $\zeta = 0.012$ (open-loop) to $\zeta = 0.295$, representing a 24.5-fold improvement in modal energy dissipation rate while consuming 48.3% lower RMS control voltage compared to standard SMC [33].

Practical Applications: These advancements enable direct application across highly demanding engineering sectors: (1) Aerospace Systems: Solar array deployment booms, satellite refueling manipulators, and space station remote manipulator arms operating in zero-gravity environments where structural weight must be strictly minimized [34]. (2) Medical and Surgical Robotics: Flexible endoscopic and minimally invasive surgical arms requiring sub-millimeter positioning accuracy within delicate organic tissues [35]. (3) High-Speed Microelectronics Assembly: Pick-and-place robots operating at high accelerations where residual settling time directly limits hourly component production throughput [36].

LIMITATIONS

Despite significant performance gains demonstrated by adaptive smart material vibration suppression, several engineering limitations must be acknowledged:

- High Voltage and Power Amplifier Constraints: Piezoelectric PZT and MFC actuators require high driving voltages (typically 100V to 500V) to generate substantial bending moments. This necessitates bulky, specialized power amplifiers, partially offsetting the weight benefits achieved by lightweight structural links.
- Sensor and Actuator Bonding Longevity: Under severe multi-axis cyclical bending stresses, high shear strain concentration develops along the adhesive interface between smart material patches and substrate beams. Interfacial debonding or structural cracking of brittle PZT ceramics over extended operating cycles leads to progressive actuation authority degradation.
- Thermal Dissipation in Dense Smart Structures: Continuous high-frequency actuation of smart material patches generates localized Joule heating and dielectric dissipation, elevating localized temperatures and temporarily altering substrate flexural stiffness and piezoelectric coupling constants.

Page 64-78 © MANTECH PUBLICATIONS 2026. All Rights Reserved

FUTURE SCOPE

To overcome current technological barriers and advance smart flexible robotic systems toward full industrial adoption, future research should focus on the following directions:

- Embedded Additive Smart Structures: Transitioning from surface-bonded smart patches to 3D-printed composite links with embedded carbon nanotube (CNT) networks and integrated piezoelectric fibers to eliminate bonding shear degradation.
- Deep Reinforcement Learning for Non-Collocated Control: Developing model-free Deep Q-Networks (DQN) and Proximal Policy Optimization (PPO) algorithms capable of autonomously learning non-linear flexible dynamics and compensating for non-collocated phase delays without requiring precise analytical dynamic models.
- Self-Powered Energy Harvesting Smart Manipulators: Integrating hybrid piezoelectric-thermoelectric energy harvesting circuits that capture waste mechanical structural vibration energy during rapid movements, storing electrical energy to power wireless onboard strain sensor arrays.

CONCLUSION

This review paper has presented an in-depth investigation into advanced vibration suppression techniques for flexible robotic manipulators using smart materials and adaptive control strategies. Lightening robotic structural links offers tremendous advantages in energy efficiency and operation speeds, but inherent link flexibility generates severe elastic vibrations that compromise positioning accuracy. Integrating surface-bonded piezoelectric ceramics (PZT) and Macro-Fiber Composites (MFC) with an Adaptive RBF Neural-Network Sliding Mode Control (ASMC) framework achieves rapid active modal damping, suppressing peak tip deflection by over 90% and reducing residual settling time from 4.65 seconds to 0.62 seconds. The adaptive controller successfully eliminates control signal chattering, preventing high-frequency unmodeled structural spillover while demonstrating exceptional robustness against 50% payload variations. By overcoming smart material hysteresis and non-collocated sensor-actuator instabilities, these advanced control techniques pave the way for next-generation lightweight industrial, aerospace, and medical robotic manipulators.
