ABSTRACT

*Concrete is the most widely used construction material across the world, but it suffers from an inherent problem of cracking which reduces durability and service life of structures. Traditional repair techniques are costly, labor intensive and sometimes impractical for hidden or micro cracks. Recently, the concept of **self-healing concrete** and **smart concrete systems** has emerged as a promising solution to enhance durability, sustainability, and structural health monitoring capabilities. Self-healing concrete has the ability to autonomously repair cracks using biological, chemical, or mineral based healing agents, while smart concrete integrates sensing capabilities for monitoring stress, strain, temperature and damage. This paper presents a comprehensive review of different self-healing mechanisms including autogenous healing, bacteria based healing, encapsulated polymers, and mineral admixtures. Further, the paper discusses smart concrete technologies such as piezoresistive materials, fiber optics sensors, and nanomaterials for real-time monitoring. Advantages, limitations, practical applications, and future research directions are also highlighted. The integration of self-healing and smart functionalities in concrete can significantly transform the maintenance strategies of civil infrastructure.*

***KEYWORDS:** Self-healing concrete, smart concrete, bacteria-based healing, microcapsules, piezoresistive sensing, durability, nanomaterials, and*

structural health monitoring.

INTRODUCTION

Concrete structures develop cracks due to shrinkage, temperature variations, overloading and environmental effects. Even very small cracks allow ingress of water, chlorides, and harmful chemicals which leads to corrosion of reinforcement and deterioration. Conventional repair methods like epoxy injection, grouting and patch repair requires manual inspection and continuous maintenance.

The idea of concrete which can **heal its own cracks** without external intervention is inspired from biological systems. At the same time, concrete which can **sense its own condition** and report damage is known as smart concrete. These two technologies together aim to make structures more durable, economical and sustainable.

Self-healing and smart concrete systems are gaining interest among researchers due to increasing demand for long lasting infrastructure with reduced maintenance cost. This review focuses on various techniques, materials and working principles of these innovative systems.

CONCEPT OF SELF-HEALING CONCRETE

Self-healing concrete is an innovative material designed to **automatically repair cracks** that develop during the service life of structures. Cracking in concrete is unavoidable due to shrinkage, thermal stresses, overloading, and environmental exposure. These cracks allow water and aggressive ions to penetrate, which accelerates corrosion and deterioration. The self-healing concept aims to **reduce maintenance**, **increase durability**, and **extend structural life** by enabling concrete to close and seal these cracks without human intervention.

The healing process may occur either through **natural internal reactions** of cementitious materials or through the addition of specially engineered agents such as bacteria, polymers, minerals, or encapsulated chemicals. Depending on the mechanism used, self-healing concrete can be classified into **autogenous** and **autonomous** healing systems.

1. Autogenous Healing

Autogenous healing is the **natural ability of concrete** to repair very small cracks when

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

exposed to moisture. This property has been observed for many years but gained attention recently for its potential use in durable construction.

This healing occurs mainly due to two phenomena:

1. **Continued hydration of unreacted cement particles** present inside the hardened concrete.
2. **Precipitation of calcium carbonate ($CaCO_3$)** when calcium hydroxide reacts with carbon dioxide in the presence of water.

Mechanism of Autogenous Healing

- When microcracks form, water penetrates inside the crack.
- The water reacts with unhydrated cement particles that were left during initial curing.
- This reaction produces additional calcium silicate hydrate (C-S-H) gel, which is the primary binding material in concrete.
- Simultaneously, calcium hydroxide present in concrete reacts with carbon dioxide from air and forms calcium carbonate crystals.
- These products gradually fill the crack and reduce its permeability.

Characteristics

- Most effective for crack widths less than **0.2 mm**.
- Requires presence of moisture for healing.
- Works slowly and may take weeks or months.
- No additional material cost, as it is a natural property.

Limitations

- Ineffective for larger cracks.
- Healing depends strongly on environmental conditions.
- Limited repeatability after several cracking cycles.

Despite limitations, autogenous healing is considered the **base mechanism** upon which advanced self-healing techniques are developed.

2. Bacteria-Based Self-Healing Concrete

Bacteria-based self-healing concrete is one of the most researched and promising autonomous

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

healing techniques. In this method, specific types of bacteria capable of producing limestone are incorporated into the concrete mix along with nutrients.

Commonly used bacteria include:

- *Bacillus subtilis*
- *Bacillus pasteurii*
- *Sporosarcinapasteurii*

These bacteria can survive in dormant form inside concrete for many years.

Working Principle

When a crack forms and water enters:

- Water activates dormant bacterial spores.
- Bacteria start consuming the provided nutrients (usually calcium lactate).
- During this metabolic process, bacteria produce calcium carbonate ($CaCO_3$).
- The limestone precipitates and gradually seals the crack.

Chemical Process:

Bacteria + Calcium lactate + Oxygen → Calcium carbonate (Limestone) + CO_2

Features

- Can heal cracks up to **0.5–0.8 mm**, which is much larger than autogenous healing.
- Healing is long-lasting and repeatable.
- Improves durability by blocking water and chloride penetration.
- Environmentally friendly as it uses natural biological process.

Challenges

- High cost of bacterial culture and nutrients.
- Difficulty in ensuring survival of bacteria in high alkaline concrete environment (pH ~12).
- Proper distribution of bacteria in concrete is required.
- Long-term field performance still under study.

To protect bacteria, they are often stored in **lightweight aggregates**, **silica gel**, or **microcapsules** before mixing into concrete.

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

3. Capsule-Based Self-Healing Concrete

Capsule-based healing is a chemical approach where **microcapsules** containing healing agents are embedded within the concrete. These capsules remain intact during mixing and hardening.

When cracking occurs:

- The crack path ruptures the capsules.
- Healing agent is released into the crack.
- The agent reacts with air, moisture, or cement compounds and hardens.
- The crack is sealed by polymerization or chemical reaction.

Table: 1

Healing Agent	Working Principle	Crack Width Healed
Epoxy Resin	Polymerizes and bonds crack	0.5–1 mm
Sodium Silicate	Reacts with $Ca(OH)_2$	0.4 mm
Silica Gel	Swells and blocks crack	0.3 mm

4. Mineral Admixture-Based Healing

Mineral admixture-based self-healing is an extension of the autogenous healing concept, where supplementary cementitious materials (SCMs) and crystalline chemicals are incorporated into concrete to **enhance its natural crack sealing ability**. These materials do not "heal" cracks in an active way like bacteria or capsules, but they **promote continuous internal reactions** that gradually densify the microstructure and block cracks and pores over time.

Commonly used mineral admixtures include:

- Fly ash
- Ground granulated blast furnace slag (GGBS)
- Silica fume
- Metakaolin
- Crystalline waterproofing admixtures

These materials are rich in reactive silica and alumina which participate in secondary hydration reactions long after the initial setting of concrete.

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

Working Principle

When cracks form and moisture enters the concrete:

1. Water penetrates through microcracks and pores.
2. Unreacted fly ash, slag, or silica particles react with calcium hydroxide ($Ca(OH)_2$) producedduring cement hydration.
3. This reaction forms additional **calcium silicate hydrate (C–S–H) gel**, which is the primary binding phase in concrete.
4. The newly formed C–S–H gel expands slightly and fills microcracks and pores.
5. In case of crystalline admixtures, insoluble crystals grow inside capillary pores and cracks, blocking water pathways.

This process continues for a long period, sometimes for several years, making the concrete denser with age.

SMART CONCRETE SYSTEMS

Smart concrete is a special type of concrete that possesses the ability to **sense, respond, and sometimes adapt** to external stimuli such as load, stress, temperature, vibration, and cracking. Unlike conventional concrete which is passive in nature, smart concrete behaves like a **self-monitoring material** capable of providing real-time information about its structural condition. This property is extremely useful for **structural health monitoring (SHM)** of bridges, buildings, tunnels, pavements, and dams where manual inspection is difficult and costly.

The smart behavior is achieved by incorporating conductive or sensing materials into the concrete matrix or by embedding sensors within it. These additions allow concrete to convert mechanical changes into measurable electrical signals.

1. Piezoresistive Concrete

Piezoresistive concrete is the most widely studied smart concrete system. The term *piezoresistive* means **change in electrical resistance due to applied mechanical stress or strain**.

Normal concrete is an electrical insulator. However, when conductive materials such as:

- Carbon fibers

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

- Graphite powder
- Carbon nanotubes (CNTs)
- Graphene
- Steel fibers

Are added in small percentages, the concrete becomes electrically conductive. These conductive particles form a network inside the concrete called a **conductive pathway**.

Working Principle

- Under no load, the conductive network has a certain electrical resistance.
- When load or stress is applied, microcracks develop or particles move slightly.
- This disturbs the conductive network.
- As a result, electrical resistance changes.
- By measuring this change, stress, strain, and damage can be detected.

This phenomenon is called the **piezoresistive effect**.

Mechanism Illustration

Load Applied → Microstructural Change → Change in Conductive Path → Change in Electrical Resistance → Damage Detection

Table: 2

Material Added	Property Achieved	Application
Carbon Fibers	Conductivity	Crack detection
Graphite	Strain sensing	Structural monitoring
CNTs	High sensitivity	Micro-crack sensing

2. Fiber Optic Sensors in Smart Concrete

Fiber optic sensing is one of the most reliable and advanced techniques used in smart concrete systems for **real-time structural health monitoring**. In this method, very thin optical fibers made of glass or plastic are embedded inside the concrete during casting. These fibers transmit light signals, and any change in strain, temperature, or deformation alters the characteristics of the transmitted light.

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

Unlike electrical sensors, fiber optic sensors work purely on light transmission, which makes them highly stable and accurate even in harsh construction environments.

Working Principle

- A light pulse is sent through the optical fiber.
- When the concrete experiences strain, crack, or temperature change, the fiber slightly deforms.
- This deformation changes the wavelength, phase, or intensity of the light signal.
- The altered signal is captured and interpreted using special instruments.

Two common techniques used are:

- **Fiber Bragg Grating (FBG):** Measures strain and temperature based on wavelength shift.
- **Distributed Optical Fiber Sensors (DOFS):** Measures changes continuously along the entire fiber length.

Parameters Measured

- Strain and stress distribution
- Temperature variation
- Crack formation and propagation
- Deflection and vibration

Advantages

- Very high accuracy and sensitivity
- Immune to electromagnetic interference and corrosion
- Long service life (can last as long as structure)
- Ability to monitor large areas with a single fiber
- Suitable for harsh and remote environments

Applications

- Monitoring of long-span bridges
- Tunnel deformation measurement
- Dam and retaining wall health monitoring

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

- Fire damage assessment through temperature sensing

Limitations

- Installation requires care during casting
- Initial instrumentation cost is high
- Skilled interpretation of data is required

Fiber optic sensors are especially useful where **continuous monitoring**is needed without physical access to the structure.

3. Nanomaterial-Based Smart Concrete

Nanotechnology has opened new possibilities in the development of smart concrete. Nanomaterials have particle sizes in the range of 1–100 nanometers and exhibit unique mechanical, electrical, and chemical properties. When these materials are added to concrete, they significantly enhance both **strength** and **sensing capabilities**.

Common nanomaterials used in smart concrete include:

- Nano-silica
- Carbon nanotubes (CNTs)
- Graphene and graphene oxide
- Nano-titanium dioxide

Role in Mechanical Improvement

- Nano-silica fills nano-pores in concrete and reacts with calcium hydroxide to form additional C–S–H gel.
- This results in denser microstructure, higher strength, and reduced permeability.
- Improves durability and resistance to chemical attack.

Role in Sensing Properties

- CNTs and graphene form highly conductive nano-networks inside concrete.
- Even very small cracks disturb this network, causing measurable changes in electrical resistance.
- This allows detection of micro-level damage much before visible cracking.

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

Contribution to Self-Healing

Nanomaterials indirectly assist self-healing by:

- Reducing pore size and crack width.
- Promoting additional hydration reactions.
- Making the concrete matrix denser, which supports autogenous healing.

Advantages

- Significant improvement in compressive and tensile strength.
- High sensitivity for crack detection.
- Better durability and longer service life.
- Works in combination with other smart and self-healing techniques.

Challenges

- High cost of nanomaterials.
- Proper dispersion in concrete mix is difficult.
- Health and safety concerns during handling of nanoparticles.

Nanomaterial-based smart concrete represents the **next generation of intelligent construction materials**, where strength, durability, sensing, and healing properties are combined at microscopic level.

INTEGRATION OF SELF-HEALING AND SMART SYSTEMS

The convergence of **self-healing materials** and **smart sensing technologies** represents a transformative step toward truly autonomous, durable, and intelligent concrete infrastructure. While self-healing concrete can repair cracks without human intervention, and smart systems can monitor structural health in real time, their **integration creates a closed-loop system** capable of *detecting damage, activating repair, and reporting recovery status*.

This synergy enables concrete structures to behave like **living systems**—sensing injury, initiating repair, and communicating health conditions to engineers.

1. Conceptual Framework of the Integrated System

An integrated self-healing smart concrete system typically consists of four interacting components:

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

A. Sensing Layer (Damage Detection)

- Embedded sensors detect early crack formation, strain changes, moisture ingress, or chemical changes.
- Sensors may include:
- Fiber Bragg Grating (FBG) sensors
- Piezoelectric transducers
- Carbon nanotube (CNT) or graphene-based conductive networks
- Acoustic emission sensors
- Humidity and pH sensors

B. Healing Layer (Autonomous Repair Mechanism)

- Healing is triggered when cracks form and environmental conditions (e.g., moisture) activate:
- Microcapsules containing healing agents (epoxy, sodium silicate)
- Bacteria-based bio-mineralization (calcite precipitation)
- Superabsorbent polymers (SAP)
- Vascular networks carrying repair agents

C. Processing & Decision Layer (Smart System)

- Data from sensors is processed using:
- IoT-enabled microcontrollers
- Edge computing devices
- AI/ML algorithms to classify crack severity
- The system decides whether healing is required and monitors healing progress.

D. Communication Layer (Reporting & Monitoring)

- Wireless transmission of data to cloud dashboards
- Engineers can remotely monitor:
- Crack initiation time
- Healing activation
- Healing effectiveness
- Long-term durability trends

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

APPLICATIONS IN CIVIL ENGINEERING

Table: 3

Structure Type	Application of Self-Healing	Smart Monitoring Use
Bridges	Crack sealing	Load and strain sensing
Tunnels	Leakage control	Deformation monitoring
Marine Structures	Corrosion prevention	Salinity detection
Dams	Long term durability	Stress analysis

ADVANTAGES OF SELF-HEALING AND SMART CONCRETE

- Reduced maintenance cost
- Increased service life
- Sustainable construction
- Early damage detection
- Eco-friendly approach
- Less human inspection required

LIMITATIONS AND CHALLENGES

- High initial cost
- Lack of standard guidelines
- Difficulty in large scale implementation
- Long term performance uncertainty
- Compatibility issues with conventional concrete

FUTURE RESEARCH DIRECTIONS

- Development of low cost bacteria techniques
- Use of AI with smart concrete data
- 3D printed self-healing concrete
- Large scale field applications
- Hybrid healing methods

Page 60-73 © MANTECH PUBLICATIONS 2026. All Rights Reserved

CONCLUSION

Self-healing and smart concrete systems represents a revolutionary development in construction materials. The ability of concrete to repair its own cracks and monitor its condition can significantly enhance durability and sustainability of infrastructure.

Although cost and practical challenges exist, continuous research is making these technologies more feasible. In future, these systems can become standard practice in construction industry, reducing maintenance problems and improving safety of structures.
